Maximal Covering by Disks

One disk

$MCD(\mathcal{P}, 1)$ is the problem of placing one disk on the plane to cover a subset of a demand set \mathcal{P} maximizing the weights of the covered points.

$$\max_q w(\mathcal{P} \cap D(q)),$$

- $\mathcal{P} = \{p_1, \dots, p_n\}$ is the demand set with weights $w(p_i) > 0$
- $w(A)$, $A \subset \mathcal{P}$, is the sum of weights of the points in A
- $D(q)$ is a unit disk with center at point q
- (M. Chazelle and Lee 1986) proposed a $\mathcal{O}(n^2)$ algorithm
- (Drezner 1981) proposed a $\mathcal{O}(n^2 \log n)$ which our work is based on
- We will introduce an equivalent problem...

Maximum Weight Clique Problem

Let $\mathcal{D} = \{D_1, \dots, D_n\}$ be a set of n unit disks with weights $w_i > 0$. The maximum weight clique is defined as

$$\max_q \sum_{D_k \cap q \neq \emptyset} w_k,$$

- The disks are fixed with centers at $\mathcal{P} = \{p_1, \dots, p_n\}$ with $w_k = w(p_k)$
- A clique is a non-empty intersection area of a subset of disks. We search for only a point in an optimal clique.
- An optimal solution for the maximum weight clique is an optimal solution for $MCD(\mathcal{P}, 1)$.

Maximum Weight Clique Problem

Algorithm

Defining $\Gamma_+(i, j)$ and $\Gamma_-(i, j)$:

Let D_i and D_j be two unit disks that intersect at two points.

- Assume D_i is at the origin
- We can find the polar angle of the intersection points. Let's call them $\Gamma_+(i, j)$ and $\Gamma_-(i, j)$ with the following condition:
 - The arc defined by $\Gamma_+(i, j)$ and $\Gamma_-(i, j)$ bounds the region $D_i \cap D_j$
- Later it will be shown how to find which one is which algorithmically.

Maximum Weight Clique Problem

Algorithm

Maximum Weight Clique Problem

Algorithm

For a disk D_i , a counter-clockwise traversal visits every $\Gamma_+(i, j)$ and $\Gamma_-(i, j)$ in counter-clockwise order.

- An intersection region of disks is bounded by arcs.
- The arc $\Gamma_+(i, j), \Gamma_-(i, j)$ (counter-clockwise) determines a region where i and j intersect.
- In a counter-clockwise traversal, the arcs where $\Gamma_+(i, j) > \Gamma_-(i, j)$ can be a problem for the implementation. The traversal is on a circle, where to start?
- If the traversal reaches a opening angle, we mark the intersecting disk as active. If it reaches a closing angle we unmark it.
- We want to find a point in the traversal with the most active disks.

Maximum Weight Clique Problem

Algorithm

For every disk, traverse the sorted list of intersection angles twice, keeping a set of active disks, and the current best solution.

Doing the traversal twice solves the problem of deciding where to start.

Maximum Weight Clique Problem

Algorithm

The run-time complexity of the algorithm is $\mathcal{O}(n^2 \log n)$.

- There are $\mathcal{O}(n^2)$ intersections among n disks
- Sorting takes $\mathcal{O}(n^2 \log n)$
- The traversal takes $\mathcal{O}(n)$ for every disk.
- It can be implemented in $K \log n$ where K is the number of intersections.

Maximum Covering by Disks

Multiple disks

Works found in the literature:

- In (Berg, Cabello, and Har-Peled 2006) a $\mathcal{O}(n^{2m-1})$ algorithm was proposed. Also a $(1 - \epsilon)$ -approximation that runs in $\mathcal{O}(n \log n)$ was introduced.
- In (HE et al. 2015) a heuristic method using an algorithm called mean-shift was developed. The mean-shift algorithm converges to a local density maxima of any probability distribution and it is used to find a smaller candidate list of centers for the disks.

Because of the similarities, we will discuss only the multiple ellipses algorithm later.

Ellipse

Given a center $c \in \mathbb{R}^2$ and $Q \in \mathbb{R}^{2 \times 2}$, an ellipse is the set of points that satisfy

$$\|u - c\|_Q^2 = (u - c)^T Q (u - c) = 1,$$

with \leq representing the set of covered points

Axis-parallel ellipse

Any 2 by 2 diagonal d.p. matrix determines an axis-parallel ellipse, which can also be described by

$$\frac{(x - c_x)^2}{a^2} + \frac{(y - c_y)^2}{b^2} = 1,$$

where (a, b) are the shape parameters and $c = (c_x, c_y)$ is the center.

Ellipses

Maximal Covering by Ellipses

One ellipse

Let $MCE(\mathcal{P}, a, b)$ be an instance of the maximal covering by one ellipse, with E being an ellipse with shape parameters $(a, b) \in \mathbb{R}_{>0}^2$, an optimal solution of $MCE(\mathcal{P}, a, b)$ is given by

$$\max_q |\mathcal{P} \cap (q)|,$$

- $E(q)$ is an axis-parallel ellipse with center point q
- Assuming unit weights for now
- Same algorithm for one disk

Maximal Covering by Ellipses

One ellipse

Maximal Covering by Ellipses

m ellipses

Let $MCE(\mathcal{P}, \mathcal{E})$ be an instance of the maximal covering by ellipses, an optimal solution is given by

$$\max_{q_1, \dots, q_m} \left| \bigcup_{i=1}^m \mathcal{P} \cap E_i(q_i) \right|,$$

- \mathcal{E} is a set of m ellipses
- (Canbolat and Massow 2009) is the very first study on the problem. Slow exact method, a heuristic one was proposed.
- (Andretta, Birgin, and Raydan 2013) proposed a method that breaks the problem into smaller optimization ones. Also, they developed a method for the non-axis-parallel case.

Maximal Covering by Ellipses

Pre-processing that finds every possible coverage for ellipse E_i

```
1:  $A \leftarrow \bigcup_{j \in I_i} \{\Gamma_+(i, j) \cup \Gamma_-(i, j)\}$ 
2:  $Z \leftarrow \{\}$ 
3: for  $cnt = 1..2$  do
4:   for  $a \in A$  do
5:     Let  $p_a$  be the point that intersects  $E_i$  at angle  $a$ .
6:     if  $a$  is a starting angle then
7:        $Cov \leftarrow Cov \cup \{p_a\}$ 
8:     else
9:        $Cov \leftarrow Cov \setminus \{p_a\}$ 
10:    end if
11:     $Z \leftarrow Z \cup \{Cov\}$ 
12:  end for
13: end for
```

Maximal Covering by Ellipses

- The algorithm for m ellipses tries every possible assignment of coverage for every one of the ellipses
- Run-time complexity of $\mathcal{O}(n^2)^m = \mathcal{O}(n^{2m})$
- Simpler than the m disks algorithm proposed by (Berg, Cabello, and Har-Peled 2006). Achieves a similar complexity ($\mathcal{O}(n^{2m-1})$).
- Small improvements can be made in the pre-processing exhibited earlier in order to reduce the size of the search space:
 - Non-maximal coverage sets.
 - Ellipses that are too distant do not need to be checked.
- The unit-weight assumption can be easily dropped

Primary goals:

- Study the $(1 - \epsilon)$ -approximation method for the planar covering with disks in (Berg, Cabello, and Har-Peled 2006) and develop an adapted version of the algorithm for ellipses with the same time complexity of $\mathcal{O}(n \log n)$.
- Develop an exact method for the version of the problem introduced in (Andretta, Birgin, and Raydan 2013) where the ellipses can be freely rotated.

Secondary goals:

- Develop a probabilistic approximation algorithm based on (Aronov and Har-Peled 2008) which proposed a Monte Carlo approximation for the problem of finding the deepest point in a arrangement of regions. The method runs in $\mathcal{O}(n\epsilon^2 \log n)$ and can be applied to solve the case with one ellipse. The case with more than one ellipse is left as a challenge for us for the next steps of our research.
- In (HE et al. 2015), the task of finding every center candidate, after eliminating all the non-essential ones, is done in $\mathcal{O}(n^5)$ run-time complexity. We want to generalize this for the elliptical distance function and achieve a better run-time complexity. We also intend to use the mean-shift algorithm to try to develop a greedy version for the ellipses version.
